Code Generation

Motivation

For good performance, the operator subscripts have to be compiled

- either byte code
- or machine code
- generating machine code is more difficult but also more efficient

Machine code has portability problems

- code generation frameworks hide these
- some well known kits: LLVM, libjit, GNU lightning, ...
- greatly simplify code generation, often offer optimizations

LLVM is one of the more mature choices.

LLVM

Distinct characteristics

- unbounded number of registers
- SSA form
- strongly typed values

```
define i32 @fak(i32 %x) {
     %1 = icmp ugt i32 %x, 1
     br i1 %1, label %L1, label %L2
L1: \%2 = \text{sub i} 32 \%x, 1
     %3 = call i32 @fak(i32 %2)
     %4 = mul i32 %x, %3
     br label %L3
L2: br label %L3
L3: %5 = phi i32 [ %4, %L1 ], [ 1, %L2 ]
     ret i32 %5
```

Compiling Scalar Expressions

- all scalar values are kept in LLVM registers
- additional register for NULL indicator if needed
- most scalar operations (=, +, -, etc.) compile to a few LLVM instructions
- C++ code can be called for complex operations (like etc.)
- goal: minimize branching, minimize function calls

The real challenge is integrating these into set-oriented processing.

Data-Centric Query Execution

Why does the iterator model (and its variants) use the operator structure for execution?

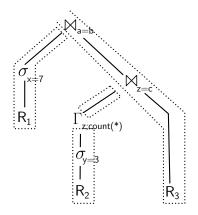

- it is convenient, and feels natural
- the operator structure is there anyway
- but otherwise the operators only describe the data flow
- in particular operator boundaries are somewhat arbitrary

What we really want is data centric query execution

- data should be read/written as rarely as possible
- data should be kept in CPU registers as much as possible
- the code should center around the data, not the data move according to the code
- increase locality, reduce branching

Data-Centric Query Execution (2)

Example plan with visible pipeline boundaries:

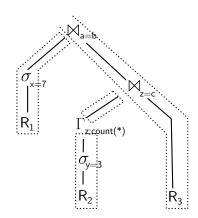

- data is always taken out of a pipeline breaker and materialized into the next
- operators in between are passed through
- the relevant chunks are the pipeline fragments
- instead of iterating, we can push up the pipeline

Data-Centric Query Execution (3)

Corresponding code fragments:

```
initialize memory of \bowtie_{a=b}, \bowtie_{c=z}, and \Gamma_z
for each tuple t in R_1
  if t.x = 7
     materialize t in hash table of \bowtie_{a=b}
for each tuple t in R_2
  if t.v = 3
     aggregate t in hash table of \Gamma_{z}
for each tuple t in \Gamma_z
   materialize t in hash table of \bowtie_{z=c}
for each tuple t_3 in R_3
  for each match t_2 in \bowtie_{z=c}[t_3.c]
     for each match t_1 in \bowtie_{a=b}[t_3.b]
        output t_1 \circ t_2 \circ t_3
```

Data-Centric Query Execution (4)

Basic strategy:

- 1. the producing operator loops over all materialized tuples
- 2. the current tuple is loaded into CPU registers
- 3. all pipelining ancestor operators are applied
- 4. the tuple is materialized into the next pipeline breaker
 - tries to maximize code and data locality
 - a tight loops performs a number of operations
 - · memory access in minimized
 - operator boundaries are blurred
 - code centers on the data, not the operators

Producing the Code

Code generator mimics the produce/consume interface

- these methods do not really exist, they are conceptual constructs
- the produce logic generates the code to produce output tuples
- the consume logic generates the code to accept incoming tuples
- not clearly visible within the generated code

Producing the Code (2)

```
void HJTranslatorInner::produce(CodeGen& codegen,Context& context) const
     Construct functions that will be be called from the C++ code
    AddRequired addRequired(context,getCondiution().getUsed().limitTo(left));
    produceLeft=codegen.derivePlanFunction(left,context);
    AddRequired addRequired(context,getCondiution().getUsed().limitTo(right));
    produceRight=codegen.derivePlanFunction(right,context);
  // Call the C++ code
  codegen.call(HashJoinInnerProxy::produce.getFunction(codegen),
    {context.getOperator(this)});
void HJTranslatorInner::consume(CodeGen& codegen,Context& context) const
  Ilvm::Value* opPtr=context.getOperator(this);
```

Producing the Code (3)

```
// Left side
if (source==left) {
 // Collect registers from the left side
  vector<ResultValue> materializedValues:
  matHelperLeft.collectValues(codegen,context,materializedValues);
 // Compute size and hash value
  Ilvm::Value* size=matHelperLeft.computeSize(codegen,materializedValues);
  Ilvm::Value* hash=matHelperLeft.computeHash(codegen,materializedValues);
  // Materialize in hash table, spools to disk if needed
  Ilvm::Value* ptr=codegen.callBase(HashJoinProxy::storeLeftInputTuple,
    {opPtr,size,hash});
  matHelperLeft.materialize(codegen,ptr,materializedValues);
```

Producing the Code (4)

```
// Right side
} else {
 // Collect registers from the right side
 vector<ResultValue> materializedValues;
 matHelperRight.collectValues(codegen,context,materializedValues);
 // Compute size and hash value
 Ilvm::Value* size=matHelperRight.computeSize(codegen,materializedValues);
 llvm::Value* hash=matHelperRight.computeHash(codegen,materializedValues);
 // Materialize in memory, spools to disk if needed, implicitly joins
 Ilvm::Value* ptr=codegen.callBase(HashJoinProxy::storeRightInputTuple,
    {opPtr.size}):
 matHelperRight.materialize(codegen,ptr,materializedValues);
 codegen.call(HashJoinInnerProxy::storeRightInputTupleDone, {opPtr,hash});
```

Producing the Code (5)

```
void HJTranslatorInner::join(CodeGen& codegen,Context& context) const
  Ilvm::Value* leftPtr=context.getLeftTuple(),*rightPtr=context.getLeftTuple();
  // Load into registers. Actual load may be delayed by optimizer
  vector<ResultValue> leftValues,rightValues;
  matHelperLeft.dematerialize(codegen,leftPtr,leftValues,context);
  matHelperRight.dematerialize(codegen,rightPtr,rightValues,context);
  // Check the join condition, return false for mismatches
  Ilvm::BasicBlock* returnFalseBB=constructReturnFalseBB(codegen);
  MaterializationHelper::testValues(codegen,leftValues,rightValues,
    joinPredicatels, returnFalseBB);
  for (auto iter=residuals.begin(),limit=residuals.end();iter!=limit;++iter) {
    ResultValue v=codegen.deriveValue(**iter,context);
    CodeGen::If checkCondition(codegen,v,0,returnFalseBB);
  // Found a match, propagate up
  getParent()—>consume(codegen,context);
```

Parallel Query Execution

Parallelism

Why parallelism

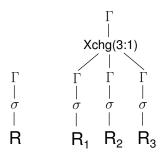

- multiple users at the same time
- modern server CPUs have dozens of CPU cores
- better utilize high-performance IO devices

Forms of parallelism

- inter-query parallelism: execute multiple queries concurrently
 - map each guery to one process/thread
 - concurrency control mechanism isolates the queries
 - except for synchronization that parallelism is "for free"
- intra-query parallelism: parallelize a single query
 - horizontal (bushy) parallelism: execute independent sub plans in parallel (not very useful)
 - vertical parallelism: parallelize operators themselves

Vertical Parallelism: Exchange Operator

- optimizer statically determines at query compile-time how many threads should run
- instantiates one query operator plan for each thread
- connects these with "exchange" operators, which encapsulate parallelism, start threads, and buffer data
- relational operator can remain (largely) unchanged
- often (also) used in a distributed setting

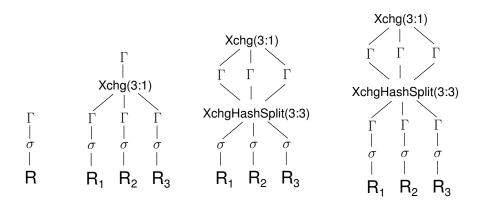

Exchange Operator Variants

Xchg(N:M) N input pipelines, M output pipelines

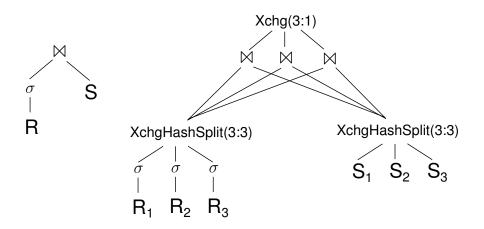

Many useful variants

- XchgUnion(N:1) specialization of Xchg
- XchgDynamicSplit(1:M) specialization of Xchg
- XchgHashSplit(N:M) split by hash values
- XchgBroadcast(N:M) send full input to all consumers
- XchgRangeSplit(N:M) partition by data ranges

Aggregation with Exchange Operators (3-way parallelism)

Join with Exchange Operators (3-way parallelism)

Disadvantages of Exchange Operators

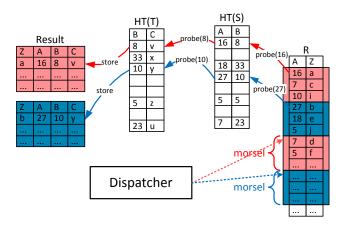

- static work partitioning can cause load imbalances (large problem with many threads)
- degree of parallelism cannot easily be changed mid-query (workload changes)
- overhead:
 - usually implemented using more threads than CPU cores (context switching)
 - hash re-partitioning often does not pay off
 - exchange operators create additional copies of the tuples

Parallel Query Engine

- alternative to Exchange Operators: parallelize operators themselves
- requires synchronization of shared data structures (e.g., hash tables)
- allows for more flexibility in designing parallel algorithms for relational operators

Morsel-Driven Query Execution

- break input into constant-sized work units ("morsels")
- dispatcher assigns morsels to worker threads
- # worker threads = # hardware threads

Dynamic Scheduling

- the total runtime of a query is the runtime of the slowest thread/core/machine
- when dozens of cores are used, often a single straggler is much slower than the others (e.g., due to other processes in the system or non-uniform data distributions)
- solution: don't partition input data at the beginning, but use dynamic work stealing:
 - synchronized queue of small jobs
 - threads grab work from queue
 - the parallel_for construct can provide a high-level interface

Parallel In-Memory Hash Join

1. build phase:

- 1.1 each thread scans part of the input and materializes the tuple
- 1.2 create table of pointers of appropriate size (tuple count sum of all threads)
- 1.3 scan materialized input and add pointers from array to materialized tuples using atomic instructions
- 2. probe phase: can probe the hash table in parallel without any synchronization (as long no marker is needed)
